Abstract

Traditionally, exploration of ecosystems in the context of undergraduate education has been restricted to connections within conventionally defined habitats (i.e., within a stream, within a forest). Further, instruction regarding the aquatic-terrestrial interface has emphasized directional inputs from land to water. However, a relatively new body of research has characterized reciprocal interactions and draws attention to fluxes from water to land, including the emergence of aquatic insects that serve as prey for terrestrial predators. We present a guide to an inquiry-based lesson for undergraduate biology that explores interactions and connections across aquatic and terrestrial habitat boundaries. The focus is on cross-habitat linkages within ecosystems, specifically, “What is the role of emergence in connecting the web of life linking aquatic and terrestrial habitats and organisms?” Students: 1) engage with a documentary film, 2) explore insect emergence and make observations of riparian insectivores, 3) explain the collected data, 4) elaborate on alternative study designs and a measure of ecosystem health, and 5) evaluate their new understanding. This lesson addresses core concepts and competencies for undergraduate biology education, identified in the Vision and Change, A Call to Action report.

Aquatic Insects, Emergence, Inquiry, Vision and Change, 5E Learning Cycle

Introduction

Ecologists have long recognized the importance of terrestrial invertebrates and plant material as inputs to streams; however, more recently the focus has turned to the
flux of materials and organisms in the opposite direction, from stream to land (Baxter et al., 2005, Sabo and Hoekman 2015). The emergence of aquatic insects in an aerial adult form represents an important link between streams and adjacent riparian habitats, facilitating the flow of energy and nutrients from aquatic to terrestrial food webs. Adult aquatic insects are important food subsidies for a range of riparian predators, including lizards, birds, bats, and spiders (Baxter et al., 2005). Some estimates indicate that only ~3% of emerged aquatic insect biomass returns to the stream to lay eggs because the majority is consumed (Jackson & Fisher, 1986). The focus here is on one specific predator because it is relatively easy to observe and identify: the spider. Populations of various spiders are known to closely track aquatic insect emergence (Marzcak & Richardson, 2007). The family Tetragnathidae, due to high mobility, can exploit short periods of emergence in localized areas. In fact, spider counts may be a useful method for assessing stream integrity and habitat quality, and are less labor-intensive than other sampling methods that use invertebrates or fish.

We present a guide for an inquiry-based laboratory and field lesson for undergraduate biology courses. The focus is on cross-habitat linkages within ecosystems; specifically, “What is the role of insect emergence in connecting aquatic and terrestrial habitats and organisms?” The challenge is to change how students think about the environment we live in: Not as an organized puzzle built from discrete pieces with defined boundaries, but rather as a colorful soup, composed of multiple layers of flavor and a taste that becomes more defined the longer you stir it.

Objectives

This lesson will teach students several of the core concepts and address competencies for biology education identified in the Vision and Change in
Undergraduate Biology Education report (AAAS, 2011). The most relevant concepts are: pathways and transformations of energy and matter (i.e. biological systems grow and change by processes based upon chemical transformation pathways and are governed by the laws of thermodynamics), and systems (i.e. living systems are interconnected and interacting). The most relevant competencies are: the ability to apply the process of science, the ability to use quantitative reasoning, and the ability to understand the relationship between science and society.

Description of Lesson

This laboratory and field lesson follows the stages of the 5E Learning Cycle:

- Engage, explore, explain, elaborate, and evaluate.

Engage

This lesson will challenge students to answer the question: “What is the role of emergence in connecting aquatic and terrestrial habitats and organisms?” The instructor should lead a discussion to elicit prior knowledge from the students, addressing the following items:

1) Name and describe the different types of biota in and around a stream or river.
2) List examples of specific connections between rivers, streams, and the land.

Have students complete a pre-assessment, drawing on ideas shared during the discussion and their own previous knowledge. Provide an image of a stream and surrounding riparian zone, and ask students to draw a diagram of an aquatic-terrestrial food web (for an example, see Figure 1). Next, have students watch the film RiverWebs. This award-winning documentary is a tribute to pioneering stream ecologist Dr. Shigeru Nakano. At heart, it is an inspiring narrative that highlights the web of ecological connections between water and land, the similarly connected community of scientists.
that extends across cultures, and the connections humans share with environments like streams and forests. Through this story, and impressive videography, students learn about the diversity of life in and around streams, as well as new ways of thinking about ecosystems. Revisit the two items discussed at the beginning of the lesson, and allow students to add to their aquatic-terrestrial food web using a different colored writing implement.

The RiverWebs DVD can be ordered through the non-profit organization Freshwaters Illustrated at http://freshwatersillustrated.org/link/RiverWebs. However, if instructors are unable to purchase this DVD, we recommend supplementing with YouTube video clips. The video clips lack the human element of the RiverWebs film, but can still add to the discussion items. Links to relevant content are provided below:

1) RiverWebs film trailer, 2:49 in length:

2) About NABS (North American Benthological Society), 5:04 in length:
   https://www.youtube.com/watch?v=dChyTqqP_cU

3) Educational segments from the RiverWebs film, 3:42 in length:
   https://www.youtube.com/watch?v=hETqlpeJiU

4) Dragonfly emergence segment from the BBC documentary Life in the Undergrowth, 2:02 in length:
   https://www.youtube.com/watch?v=CylF7eX6qmo.

Lastly, because an understanding of the ecological linkages being explored requires recognition of how the life cycles of insects connect land and water, challenge students to build a concept map of insects in different stages of their life cycles using photos (see the Penobscot County SWCD [1994] identification guide for a selection of
images). It is important to distribute the photos in a random stack, allowing students to create the connections and groupings themselves. Ask students to share and compare their concept maps. Discuss the process of metamorphosis, and describe the complex life cycles of aquatic insects. Hemimetabolous insects (from orders such as Ephemeroptera, Odonata, and Plecoptera) undergo incomplete metamorphosis. The wings develop externally and the immature individuals (called instars) have legs.

Holometabolous insects (from orders such as Coleoptera, Trichoptera, and Diptera) undergo complete metamorphosis. The wings develop internally, and the immature individuals (called larvae) resemble worms. This concept mapping activity is intended to be a discovery experience. It is unlikely that students will recognize the images of immature and adult forms as the same organism; the surprise will generate interest, and prompt students to revisit and modify their concept maps.

**Explore**

For students, the *explore* stage is an opportunity to foster a sense of discovery and act the part of a scientist. For instructors, it is a time to guide and facilitate, providing background information and resources, but challenging students to develop a hypothesis and study design themselves. The question “What is the role of insect emergence in connecting aquatic and terrestrial habitats and organisms?” should be addressed. Field investigations will require access to a local river or stream; they may be carried out as a class, in small groups, or individually. The following information is intended for the instructor, but may be disclosed to students as well.

Emerging aquatic insects can be sampled using floating emergence traps adapted from Malison et al. (2010), or sticky traps (Smith et al., 2014). The floating traps are constructed from a frame of PVC pipe, with swimming pool noodles wrapped around
the base, and a fine mesh tent to capture insects (Figure 2). Floating traps need to be
secured to a post or rebar when set out in the water. Insects can be collected in the
bottom of the bottle trap (if used), which can be detached and brought back to the
laboratory. However, we recommend that students collect the adult insects from the
traps using an aspirator (Carolina Biological Supply, Burlington, NC, U.S.A.). The sticky
traps are constructed from petri dishes coated with adhesive, and attached to a PVC
pole with Velcro (Figure 3). Traps can be spaced along the bank, and in the water of a
shallow stream or river, with the base of the pole driven securely into the ground.
Insects should collect in the sticky petri dishes, which can be detached, covered with
lids, and brought back to the laboratory. Both trap types are established, scientific
methods for sampling emergence (Malison et al., 2010; Smith et al., 2014).

Students must provide a justification for their proposed study design, showing
evidence of background research and planning, and explain the reasoning behind the
following decisions:

1) What type of emergence trap will you use?
The advantage of the floating traps is the ability to observe live insects and
collect good, whole specimens. Floating traps can be deployed in the river or stream,
and partly onto the bank. Sticky traps can be set up on the bank or in shallow water,
and are relatively easier to build and transport.

2) Where will you set the emergence traps, and how many will you use?
Trap placement is important, as emergence varies with distance from stream
edge and between pool and riffle habitats (Malison et al., 2010). Floating traps set mid-
channel collect proportionately more insects of the orders Trichoptera, Ephemeroptera,
and Diptera, whereas traps set against the bank collect proportionately more Plecoptera
(Malison et al. 2010). Emergence can be greater from pool versus riffle habitats (Iwata 2007), but can also be high from habitats like floating mats of algae or aquatic vegetation (Power et al. 2004), and certain taxa may prefer one habitat type to the other (Malison et al. 2010). There are many spatial aspects of emergence that students can explore, not only between stream reaches but also within a single reach.

3) When will you sample, and how long will the emergence traps be set for?

In many temperate watersheds, the best time of year to sample is the spring, when emergence rates are high (Nakano and Murakami 2001) and there is a strong chance of trap success. However, emergence is a year-round phenomenon, and some insects (e.g., winter stoneflies from the family Capniidae) only emerge in the middle of winter and may provide a crucial, seasonal food resource to streamside predators such as resident birds (Nakano and Murakami 2001). Depending on time constraints set by the instructor, there are numerous temporal aspects of emergence that students can investigate. To obtain a representative sample from the emergence traps though, we recommend setting them for a period of 1-3 days.

To answer the question “What is the role of insect emergence in connecting aquatic and terrestrial habitats and organisms?” students need to go beyond collecting aquatic insects and quantitatively measure the connection from the terrestrial side. We recommend counts of spiders. A procedure is described here, but students can also search the literature and review other methods (e.g., study by Benjamin et al. [2011]), who measured effects of nonnative trout on riparian spiders via reduced insect emergence, provides a good example). In either case, instructor supervision may be required as spider surveys are best conducted after sunset. Students will need a 10 m length of string or a measuring tape, a good flashlight or headlamp, a classification key...
(see Figure 4 for an example), and a data sheet (see Figure 5 for an example). A transect (i.e., a straight line path that can be walked along) should be established 10 m upstream and 10 m downstream from an insect trap. Students need to walk the transect line and scrutinize the area 2 m on either side of the line, looking for spiders and webs. Several dominant families of web-weaving spiders can be identified to the family level with relative ease, based upon body form and web characteristics (Figure 4). Explain

At this stage, students must organize, process, and make sense of information gathered in the field. Collected insects should be identified to the order level with a classification key (Stroud Water Research Center, 2015; and see Figure 6), and the information recorded. Instructors can ask students to develop their own data sheet or supply a template (Figure 5). Students need to analyze, summarize, and present the data comparing the insect and spider assemblages. There are different methods for completing these tasks (see Figure 7 for one example), and students should defend their choice with a list of advantages and disadvantages. Elaborate

Ask students to propose a new study design to answer these additional questions:

1) How different is the insect assemblage between streams and rivers within the same watershed?

2) When does the highest rate of insect emergence occur?

3) How far do emergent adult insects disperse away from a stream?

As a class, reanalyze the collected data with a focus on members of the insect orders Ephemeroptera, Plecoptera, and Trichoptera (EPT), which are widely regarded as indicators of healthy aquatic habitats (Barbour et al. 1999). Additionally, explain that...
other taxa (e.g. Chironomid midges and the order Diptera) are pollution tolerant species.

Given this new information, have students evaluate the health of the stream or river being investigated.

**Evaluate**

Challenge students to critique the study design, identifying areas of weakness, suggesting improvements, and determining the validity of their results. As a post-assessment, have students draw a second diagram of an aquatic-terrestrial food web and compare it to their initial depiction. Present the image of the food web featured in the RiverWebs film (Figure 8), and revisit the question: “What is the role of emergence in connecting aquatic and terrestrial habitats and organisms?”

**Conclusion**

The interface between aquatic and terrestrial habitats is bridged by flows of many materials and organisms; this complex web continues to be untangled by scientists, and presents an engaging mystery for students to investigate. Through this lesson, students not only act and think as scientists do, but learn a set of concepts and competencies fundamental to biology education (AAAS, 2011; Brownell et al., 2014). These are:

1) Pathways and transformations of energy and matter: Students learn this concept by drawing food webs to show the movement of resources between organisms and trophic levels.

2) Systems: Students learn this concept by measuring the spider and insect assemblage of a stream reach to demonstrate that within an ecosystem, interactions among individuals form dynamic networks.
3) The ability to apply the process of science: Students build competency in this area by designing and carrying out an investigation to answer a scientific question.

4) The ability to use quantitative reasoning: Students build competency in this area by analyzing collected data, and using statistics or other tools to answer a scientific question.

5) The ability to understand the relationship between science and society: Students build competency in this area by using the EPT taxa and riparian spiders as indices to assess habitat quality and overall health of a stream or river.

Acknowledgements

We thank A. Caruso and J. Rubbo from the Cary Institute of Ecosystem Studies for their expertise and valued discussions. We thank R. J. Smith for comments and suggestions that greatly improved the manuscript. We also express our gratitude to the science classrooms in Pocatello, ID who allowed us to implement this activity, with a special thanks to Grace Lutheran School and C. Casselman for allowing us to use multiple class periods to develop and refine this field investigation. We also acknowledge support from NSF-EPSCoR (IIA-1301792) and Idaho State University.

How to Build a Floating Emergence Trap

**Materials**

- 5 PVC pipe 90° slip elbows
- 2 PVC pipe 90° tees
- 4 PVC pipes 1 ft long
- 2 PVC pipes 2 ft long
- 2 PVC pipes ~1.5 ft long
- 2 swimming pool noodles
- sharp knife/scissors
- clear duct tape
- piece of 250 μm mesh, 5 ft x 5 ft
- 6 small alligator clips
- 2 clear pop bottles
- ethanol
- 5 ft length of paracord
- wood or metal stake

**STEP 1**

Assemble the PVC pipe frame.

**STEP 2**

Assemble the bottle trap.

**STEP 3**

Float base and mesh tent. Attach bottle trap to opening here.

For a video tutorial of a similarly designed trap, see Cadmus (2012).

Figure 2. Guide to how to build a floating insect emergence trap.
How to Build a Sticky Trap

Materials
- 1 PVC pipe, 4 ft long
- 6 petri dishes with lids
- Tangle-Trap® adhesive
- adhesive velcro strips

Assemble sticky trap. The number of petri dishes is variable.

Attach dish to pipe with velcro strips

For a more detailed description of the trap design, see Smith et al. (2014).
